ACKNOWLEDGEMENTS

I would like to extend my sincere gratitude to my supervisor, Mr. Samadhi Rathnayake, and co-supervisor, Mr. Amila Alexander, from the Faculty of Computing, for their valuable advice and assistance as I begin my research project. Their insightful feedback and constructive criticism have been crucial in increasing the focus and the quality of my research.

I also extend my appreciation to the staff of the Faculty of Computing for their assistance and encouragement as I begin this research journey.

Furthermore, I would like to acknowledge the contribution of my fellow team members for their support and collaboration. Our discussions and knowledge-sharing have been invaluable in expanding my understanding of the research topic.

Finally, I want to express my gratitude to everyone who volunteered to assist in this research. Their openness to sharing their experiences and viewpoints will be essential in assisting me in developing a deeper grasp of the topic.

DECLARATION

I declare that this is my own work, and this proposal does not incorporate without acknowledgement any material previously submitted for a degree or diploma in any other university or Institute of higher learning and to the best of my knowledge and belief it does not contain any material previously published or written by another person except where the acknowledgement is made in the text.

Name	Student ID	Signature
Niwarthana K.D.Y	IT22888716	

The above candidates are carrying out research for the undergraduate Dissertation under my supervision.

ABSTRACT

Robotic object sorting is an important component of modern automation, but there exist limitations in human–robot collaboration, transparency, and consistency. The majority of traditional systems provide accurate sorting but are unintelligible, resulting in reduced operator confidence as well as flexibility to operate in real-world scenarios. To address this, the paper presents a hybrid Explainable Artificial Intelligence (XAI)-based Recommendation System blending reasoning-based recommendations with explainable explanations for robotic sorting.

The architecture has two core modules: (i) a Recommendation Module, learned on an especially designed image dataset object-featured, occurrence, location, and reason-dependent ordered-labeled dataset, which generates adaptive, real-time ordering policies, and (ii) an XAI Layer that provides human-understandable explanations of each recommendation in text, visual overlays, and even optional speech. RGB camera image and preprocessed image features are the bases for object recognition, spatial and relational information extraction, and dynamic updating of sorting priorities. Interactive interfaces provide human operators with the ability to query and confirm decisions to enhance transparency and trust.

Expected outcomes include increased sorting accuracy, efficient task execution, and improved human–robot trust. The system relies on explainable machine learning and reasoning-based heuristics to be resilient in unstructured environments while offering explainability. End-user feedback will evaluate understanding, trust, and collaboration, reflecting advantages over traditional blackbox systems. Existing research sets out a new paradigm bridging the gap between robot precision and human wisdom, paving the way for adaptive, explainable robotic systems for industry applications.

1. INTRODUCTION

1.1. Background & Literature survey

1.1.1. Background

Robotic sorting systems have become a vital part of modern automation, enabling industries to handle a wide range of materials efficiently and accurately. Their applications span from manufacturing and agriculture to recycling and logistics, where the ability to classify and separate objects with speed and precision is essential for productivity. However, despite significant advancements in robotics and artificial intelligence (AI), real-world deployments of sorting robots still face numerous challenges. These challenges are particularly evident in environments characterized by diverse textures, dynamic human interactions, and varying operational conditions.

One of the primary technical challenges in robotic sorting is accurate material recognition when faced with varied surface textures and environmental variability. Traditional machine vision systems often struggle to maintain consistent classification performance under changing lighting conditions, background noise, or with objects of irregular shapes and surfaces [1], [2]. These limitations are especially problematic in industrial and waste-sorting applications where materials are not standardized and may exhibit considerable wear, contamination, or deformation. Conventional feature-extraction methods tend to fail under these conditions, highlighting the need for more robust and adaptive approaches.

Another significant obstacle lies in the adaptability of robotic sorting systems to dynamic and unstructured environments. In many real-world scenarios, objects arrive in unpredictable orientations, overlapping with others or partially occluded, which complicates both detection and classification tasks. Furthermore, environmental factors

such as dust, moisture, or mechanical vibrations can introduce additional noise into sensor readings, reducing system reliability. These challenges necessitate the integration of advanced sensing modalities—such as multispectral imaging, depth sensing, and tactile feedback—with AI-driven decision-making models that can adapt to such variability in real time.

In addition, human–robot interaction presents an important consideration for industrial sorting systems, especially in collaborative workspaces where robots operate alongside human workers. Robotic systems must not only identify and sort objects accurately but also anticipate and adapt to changes in human workflows, safety requirements, and operational priorities. Traditional static algorithms are insufficient for these contexts, as they cannot adjust to fluctuating task demands or unexpected operator interventions. Incorporating adaptive behavior modeling, multimodal communication channels, and explainable AI frameworks can enhance trust, transparency, and overall system efficiency in such collaborative environments.

Collaborative Texture Recognition

Recent research suggests that deep learning techniques, particularly Convolutional Neural Networks (CNNs), offer a powerful solution for texture recognition in such environments [3]. CNNs are capable of learning hierarchical representations of visual and sensor-based inputs, enabling them to identify subtle texture differences that might be overlooked by traditional algorithms. To further enhance performance and reduce the requirement for extensive training data, transfer learning with pre-trained models such as ResNet can be employed. Transfer learning allows the system to leverage prior knowledge from large-scale image datasets and adapt it to domain-specific sorting tasks [1]. Additionally, our approach integrates sensor-driven machine learning, combining visual inputs with other sensing modalities such as tactile and proximity sensors for improved recognition accuracy.

To address uncertain classification cases, the system incorporates human-in-the-loop feedback mechanisms. When the robot encounters ambiguous objects, it actively seeks input from human operators. This interaction not only improves immediate decision-making but also supports incremental learning, allowing the system to continuously refine its classification models over time. Furthermore, when labeled data is limited, Reinforcement Learning (RL) is applied to optimize sorting policies. RL enables the robot to learn effective decision-making strategies through trial-and-error interactions with the environment, gradually improving its accuracy even in data-scarce scenarios [5].

Human-Robot Collaboration and Adaptability

Beyond technical recognition capabilities, the efficiency of sorting systems depends heavily on the adaptability of robots to human behaviors. In many real-world applications, robots and humans work side-by-side, with humans often adjusting their strategies based on task requirements, time constraints, or personal preferences. Traditional robotic systems are typically static, operating according to pre-defined rules, and are therefore unable to adjust to changes in human workflow [4].

Our proposed system addresses this by monitoring human behavior through visual and interaction data, using clustering and change detection algorithms to detect shifts in sorting strategies [6]. For example, if a human operator begins grouping objects by a newly prioritized feature, the robot dynamically updates its sorting logic to complement the human's approach. This adaptability ensures a fluid division of labor, where the robot and human can work simultaneously without interfering with each other's tasks. Such adaptability is essential for collaborative robotics (cobots), where the goal is not to replace human labor but to augment it, combining human flexibility with robotic precision [6].

The integration of behavior-adaptive algorithms also improves task allocation efficiency. By reallocating sorting responsibilities based on real-time observations, the system

reduces bottlenecks, minimizes idle time, and improves overall throughput. This human-centered approach makes the robot a responsive partner rather than a rigid machine.

Multimodal Communication and Interaction

Effective communication remains a bottleneck in human-robot collaboration. In complex sorting environments, misinterpretation of commands or intentions can lead to inefficiencies or errors. Our framework addresses this by integrating multimodal sensors, including gaze tracking [7], microphones, and visual recognition systems. Gaze tracking enables the robot to infer the operator's attention focus, while microphones capture verbal instructions, which are processed using Natural Language Processing (NLP) models such as BERT [8].

This multimodal fusion allows the robot to interpret both visual and linguistic cues simultaneously, significantly reducing ambiguity in communication. For example, if a human says "sort these over there" while looking at a pile of objects, the robot uses gaze direction to determine "these" and spatial mapping to identify "over there." Adaptive dialogue management further refines communication by clarifying uncertain instructions through targeted questions, ensuring that the robot's understanding aligns with the human's intent.

The result is a more intuitive interaction between humans and robots, enabling seamless coordination even in fast-paced or noisy environments. This enhances not only task efficiency but also operator satisfaction and trust.

Explainable AI for Transparency and Trust

While technical performance is crucial, transparency in robotic decision-making is equally important for building trust in human-robot collaboration. When a robot's actions appear opaque or arbitrary, human operators may hesitate to rely on it, reducing overall system

effectiveness [9]. To address this, our system integrates Explainable AI (XAI) approaches that combine interpretable machine learning models with rule-based heuristics.

The robot is capable of generating natural language explanations for its actions, supplemented by visual or voice cues to provide additional clarity. For instance, when sorting an object, the robot might explain, "I classified this as plastic due to texture patterns detected by the sensor and confirmed by weight measurement." Additionally, the system supports interactive queries, enabling users to ask why certain actions were taken and receive context-aware explanations [10].

This level of transparency fosters mutual understanding and trust, which is essential for safe and efficient collaboration. By aligning robotic decisions with human expectations and providing clear rationales, XAI bridges the gap between human intuition and robotic precision.

Integrated System Overview

The proposed system represents a comprehensive solution to the major challenges faced by robotic sorting in real-world, human-centered environments. By combining advanced material recognition, human-adaptive behavior modeling, multimodal communication, and explainable AI, we create a robot that is not only technically capable but also socially intelligent.

The system's continuous learning framework ensures that it evolves alongside its human partners, adapting to changing strategies, improving its classification models, and refining communication protocols. This dynamic interplay between human and robot fosters higher efficiency, reduces sorting errors, and promotes a more natural teamwork experience.

Ultimately, our approach moves beyond the paradigm of robots as isolated tools toward a vision of true cooperative automation—where humans and robots collaborate as equal

partners to achieve shared goals efficiently, safely, and transparently. By addressing the limitations of existing systems and incorporating the strengths of both human adaptability and robotic precision, we aim to unlock new potential for complex sorting tasks across industrial, agricultural, and service domains. Our objective is not to replace human workers, but to create a synergistic framework in which both humans and robots can coexist and thrive—leveraging their respective strengths to enhance productivity, well-being, and long-term sustainability.

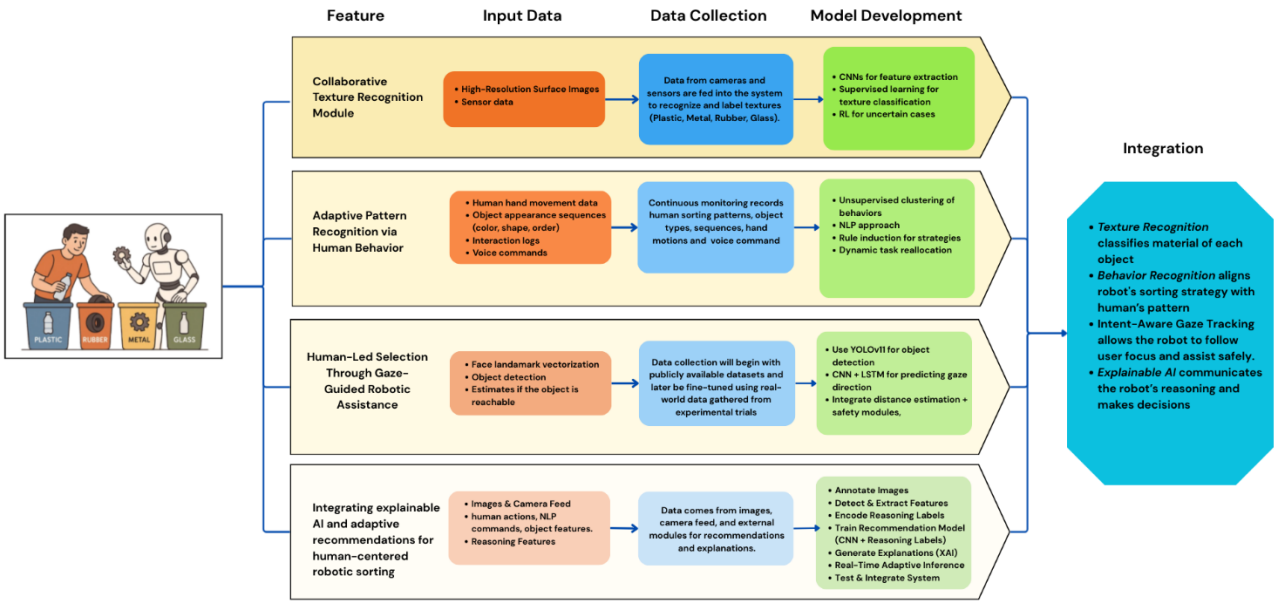

Figure 1.1: Overall system Architecture Diagram combination of all four components

1.1.2. Literature Review

1.1.2.1. Human–Robot Collaboration in Object Sorting

The evolution of sorting technologies has moved from purely manual processes to semi-automated systems and more recently to advanced robotic systems. Sorting operations in warehouses, recycling facilities, and factories have conventionally depended heavily on human intervention due to their capacity to change and make choices. But with the move of industries worldwide towards scalability and efficiency, robot sorting systems run by automation have begun to make their presence felt, driven by robotics, machine vision, and AI. For instance, Amazon Robotics has transformed warehouse operations by dispatching mobile robots to sort and transfer goods, freeing human labor for repetitive tasks. These advancements can also be seen in logistics organizations such as DHL and recyclers such as ZenRobotics employing AI-driven robots to recognize and sort out waste streams [1], [2]. These advancements are progressing towards more intelligent and responsive robotic sorting technology with the ability to reduce cost and efficiency in dynamic settings.

Despite such advancements, the transition to shared systems from complete automation is the watermark in robotics. Collaborative robots, or cobots, are designed to coexist in workplaces safely with humans, unlike other industrial robots that must be kept at bay for safety reasons. Cobots have increasingly been utilized in assembly lines and sorting functions where human flexibility and robotic precision can complement each other [3]. Research has shown that cobots comprised approximately 5% of industrial robot sales in 2018, and the figure is expected to rise to 13% by 2022, with the global cobot market forecast to rise to nearly USD 2 billion by the year 2030 [4]. This is an indication of growing industrial recognition of HRC as a productive framework for object sorting and related manufacturing processes.

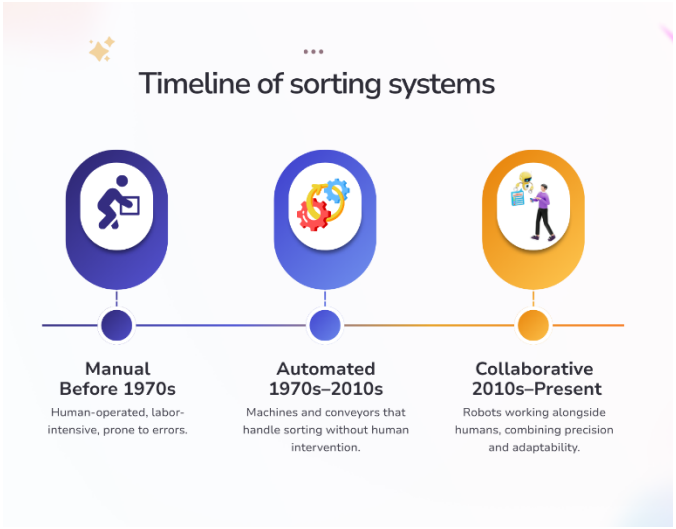

Figure 1.2: Figure of the timeline of sorting systems

1.1.2.2. Robotic Perception and Manipulation

The functioning of robotic sortation systems is heavily dependent on perception and manipulation skills. Object detection methods based on deep learning are the cornerstone of robotic perception using models like You Only Look Once (YOLO), Faster R-CNN, and Single Shot MultiBox Detector (SSD) being common [5]. These models allow for real-time object localization and classification fundamental for proper robotic grasping. Moreover, modern sorting robots increasingly use visual input together with depth sensors (RGB-D) to estimate object pose, plan appropriate grasps, and generate collision-free trajectories [6]. For example, an RGB-D-based robotic system tested on AUBO manipulators exhibited the ability to detect, locate, and grasp a range of objects autonomously, which demonstrated the power of pairing computer vision with robotic manipulation [6].

In addition to visual perception, tactile sensing is increasingly important in order to improve grasp success rates. Recent studies have emphasized visuo-haptic object perception, whereby robots integrate vision with tactile sensing to identify object properties such as texture, stiffness, and weight. This multimodal sensing approach provides more flexibility in unstructured environments where vision may not be sufficient [7]. Moreover, agile sorting technology also emerged within the recycling sector, where robots implement hybrid strategies such as push-and-drop or pick-and-release, assisted by fast trainability detection models that react differently to changing illumination and backgrounds [8]. This is a process significantly improving sorting accuracy in constantly changing conditions where items are very diverse.

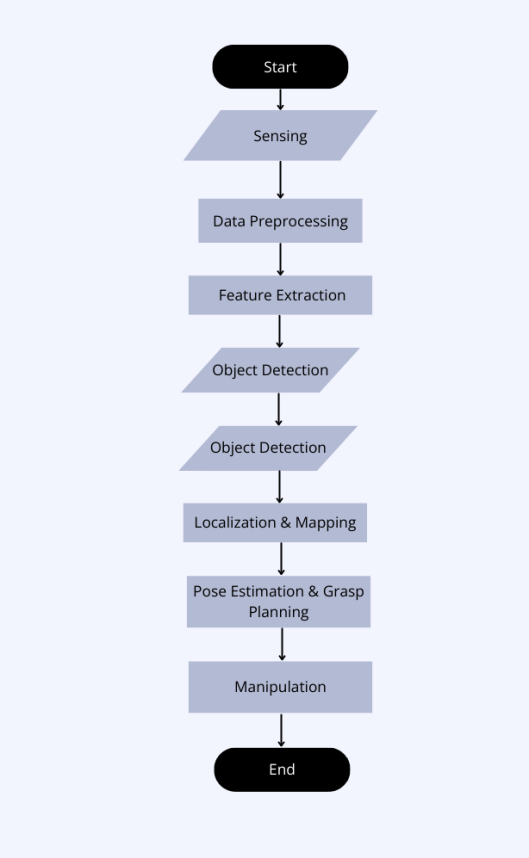

Figure 1.3: Flow of the Robo perception system

1.1.2.3. Human–Robot Collaboration (HRC)

Human–robot collaboration transcends spatial cohabitation to cognitive and decision-making integration. Cobots demonstrate this paradigm by supporting shared autonomy wherein people and robots divide tasks according to their strengths. People contribute flexibility, context understanding, and problem-solving, while robots provide speed, precision, and repeatability [3]. Adaptive collaborative control structures suggest that robots should not be passive machines but active partners capable of executing autonomous decisions through the integration of human inputs [9]. The structure is contrary to traditional master–slave control strategies and is an advancement towards collaboration at the cognitive level.

The integration of machine learning (ML) is also a factor that enhances HRC by enabling robots to anticipate human actions, learn through demonstration, and modify task execution strategies. A systematic review conducted in 2022 revealed that ML-based collaboration models increasingly emphasize time-dependent behavior, human state estimation, and environment awareness, which are crucial for industrial HRC applications [10]. Moreover, the design of the collaborative workspace has become ergonomically, inclusive, and socially created taking into account safety and comfort with the same level of efficiency [11]. Ergonomic structures have a tendency to incorporate motion planning, physical human–robot interaction (pHRI) control, and real-time safety monitoring in an effort to reduce worker fatigue and maximize cooperation [12].

Object handover is one of the most challenging but essential HRC issues. Pre-programmed handover points are utilized by most robots, which degrades fluency and increases human workload. Recent research emphasizes the need for robots to adaptively determine handover strategies as a function of human preference, object type, and situational context

[13]. Similarly, transparency and trustworthiness have been identified as essential to successful HRC. According to studies, employees resist unclear decision-making procedures, a characteristic that has been described as "algorithm aversion." Therefore, robots are likely to provide explainable feedback in order to enable humans to acknowledge the reasonableness of their decisions [14].

1.1.2.4. Existing Technologies, Sensors, and Hardware

In addition to theoretical and methodological human–robot collaboration advancements, the practical implementation of robotic sorting systems relies on sensing technology, robotic arms, and empowering hardware platforms. All these technologies constitute the foundation for perception, actuation, and human–robot safe collaboration.

Sensing technologies constitute the backbone of robot sorting. RGB and RGB-D cameras (e.g., Intel RealSense, Microsoft Azure Kinect) have been employed widely for object detection and pose estimation since they are capable of capturing visual and depth information [16]. Depth sensors with structured light or time-of-flight sensors allow robots to localize objects accurately in 3D space For finer control, force and torque sensors implanted within the robot wrist provide feedback on contact forces, which is necessary for delicate object handling and human-to-robot handovers [17]. In addition, tactile sensors implanted in robotic grippers enable the recognition of object surface features like texture and compliance, thereby enhancing grasp reliability [18]. Advanced research also explores multimodal sensing integration, where vision, force, and touch inputs are combined to facilitate perception of cluttered and dynamic environments.

At the hardware level, collaborative robot arms such as the Universal Robots UR series, ABB's YuMi, and FANUC CRX models have become standard platforms for HRC research. These robots are provided with joint torque sensors certified for safety and soft

collision detection capabilities in order to interact with people without enclosures [19]. Gripper technologies have also leapfrogged from parallel-jaw grippers to industrial components to adaptive, anthropomorphic hands such as the Robotiq 2F-85 or Shadow Dexterous Hand, capable of dealing with diverse objects. Soft and air grippers have also been designed to handle fragile or asymmetrically shaped items and are specifically relevant in streams of waste or food products sorting [20].

Automated sorting machines also require computer hardware to support perception and decision-making. GPUs and specialized AI accelerators (e.g., NVIDIA Jetson AGX Xavier, Google Coral TPU) are normally applied onboard robots to run deep learning models in real-time [21]. Edge computing allows robots to be independent without computation involving clouds, particularly needed in dynamic industrial settings where latency must be kept low.

Finally, interaction and safety technologies play a critical role in collaborative sorting. Proximity sensors, LiDAR scanners, and 3D vision-based detection systems enable robots to detect the presence of humans and slow down or alter motion accordingly. These devices, controlled by ISO 10218 and ISO/TS 15066 safety standards, enable robots to decrease force adaptively and stop when human operators approach the workspace [22]. With the integration of perception sensors, compliant manipulators, and real-time computation, current technologies provide a basis for constructing advanced human–robot collaborative sorting systems.

1.1.2.5. Challenges in Current Systems

Despite the impressive developments in robot sorting systems, several limitations still prevail. To begin with, adaptability to changing environments poses a serious challenge. Real-world sorting is often characterized by diverse object geometries, occlusions, and environmental conditions. Although deep learning algorithms are extremely accurate in

regularized environments, their performance is compromised in dynamic or new situations unless they are retrained. Agile methods such as quick model adaptation and human-corrected correction have been proposed to address this issue [8]. Indeed, experiments show that human interaction, i.e., occlusion removal or grip pose adaptation, can increase sorting accuracy from ~33% to ~100%, showing the benefit of hybrid collaboration [15].

Secondly, inexplicability of robotic decision-making demoralizes trust and transparency. The majority of sorting robots are "black boxes," where human beings can't comprehend why specific objects were sorted or treated in specific way. Explainable AI (XAI) frameworks are therefore required to make the decision-making process clear so that human workers can build up trust and work effectively alongside robots [14].

Thirdly, optimization of efficiency still remains challenging where there are multiple kinds of objects. Bots find it hard to optimize the prioritization of objects or acquire task strategies in complex situations. Furthermore, methods based on data such as reinforcement learning, as promising as they are, have limitations such as sample inefficiency, sparse rewards, and sim-to-real gap [13]. Safety and ergonomics concerns also remain: cobots tend to be slower than traditional robots due to safety constraints, which could impair throughput if addressed through sophisticated control and scheduling algorithms [11].

1.1.3. Explainable Artificial Intelligence (XAI) in Robotics

1.1.3.1. Introduction to XAI

Explainable Artificial Intelligence (XAI) has been a central research focus in recent years, especially since artificial intelligence systems are being employed to support decision-making for safety-critical domains such as healthcare, finance, and robotics. While traditional AI models—and deep learning architectures especially—provide state-of-the-art performance for object detection, classification, and decision-making, they behave like "black boxes" whose rationale is not known to the end users. This lack of transparency is especially troublesome when robots are being deployed in environments in which they will need to cooperate with humans, since humans will struggle with robotic decisions being difficult to understand, anticipate, or trust [23]. Seeking to resolve these challenges, the Defense Advanced Research Projects Agency (DARPA) established the XAI program in 2016, in which explainability was explicitly designed as the ability of a model to facilitate its decision-making processes to be understandable by humans [24].

In general, explainability methods can be categorized into intrinsic approaches—where interpretability is built into the model design itself (e.g., linear models, decision trees, symbolic reasoning)—and post-hoc approaches, where explanations are generated after a model has already produced predictions, i.e., visual heatmaps or feature attributions [25]. Intrinsic methods are generally simpler but limited for addressing complex tasks like robot vision, while post-hoc methods allow complex deep learning models (e.g., convolutional neural networks) to be partially interpretable without sacrificing accuracy. For robotics, both kinds are essential: intrinsic ones help in transparent task planning, and post-hoc ones interpret perception and recognition tasks.

1.1.3.2. XAI Methods for Perception Tasks

One of the most extensively researched uses of XAI in robotics is visual perception operations like object detection and classification, which form the foundation of robotic sorting and manipulation. These have been successfully employed with more recent studies, such as perturbing input features to find their contribution towards predictions with Local Interpretable Model-Agnostic Explanations (LIME) and SHapley Additive exPlanations (SHAP), which utilizes importance scores over each input variable derived through cooperative game theory [26]. For image-based robotics vision tasks, techniques like Gradient-weighted Class Activation Mapping (Grad-CAM) have proved to be extremely helpful as they create heatmaps throughout an image to show which areas affected the model's classification the most [27].

In sorting robots, for example, Grad-CAM can highlight the specific edges, textures, or colors that resulted in the vision system classifying an object as a recyclable plastic bottle instead of metal scrap. This not only helps engineers debug model actions but also helps operators understand why the robot acted in a certain way, increasing collaboration. Evidence from post-2021 research has demonstrated the effectiveness of combining SHAP with deep vision models such as YOLOv7 and EfficientDet for real-time interpretability in robotic perception systems [28]. These methods ensure that explanations remain in accordance with human-identifiable visual aspects, thereby bridging the gap between robotic reasoning and human understanding. Recent studies demonstrate the effectiveness of Grad-CAM in robotic manipulation tasks, showing that such explanations not only help developers debug models but also allow human collaborators to validate robot decisions in real time [29].

1.1.3.3. XAI in Decision-Making

Aside from perception, robots need to make higher-level decisions about task accomplishment, order, and collaboration. Traditional interpretable models such as decision trees and rule-based systems provide explainable mechanisms for reasoning but are not generally flexible enough to deal with adaptive environments [30]. More current research integrates reinforcement learning with symbolic reasoning or heuristic rules in an attempt to find a compromise between adaptability and interpretability [31]. For example, warehouse robots in logistics have been equipped with hybrid AI systems where deep reinforcement learning governs object assignment and decision trees provide interpretable explanations to operators [32]. The hybrid allows tracing back the decision, such as why a robot placed a fragile object on top of another, for purposes of accountability and efficiency.

1.1.3.4. XAI in Human-Robot Interaction (HRI)

In Human-Robot Collaboration (HRC), explainability has a direct consequence on trust, safety, and collaboration. Studies show that robots providing explanations of the task they perform result in higher human trust and improved task coordination [33]. In healthcare, treatment-recommending assistive robots that explain increase patient compliance and caregiver confidence [34]. Autonomous vehicles also included natural language explanations of route decisions so that passengers can understand safety-driven maneuvering [35]. In warehouse robotics, robots in industry increasingly apply XAI to explain why they select particular objects for sorting, reducing the contribution of human error and the potential for disturbances in the workflow [36]. These applications demonstrate not only how XAI enhances technical robustness but also how it supports the social dimension of HRI, enabling more seamless human-robot integration into human-centered spaces.

1.1.3.5. Limitations of Current XAI Approaches

Despite progress, existing XAI methods are drastically impaired in their application to robotics. Firstly, most methods are designed for classification (for example, image classification) rather than decision-making in a dynamic environment [37]. For instance, while Grad-CAM can explain why the robot has identified an object, it cannot explain why the robot chose a specific sequence of actions. Second, real-time needs are still a problem, as the majority of XAI techniques are computationally intensive and difficult to apply on time-demanding robot systems [38]. Lastly, there have been limited studies on using XAI for optimization and recommendation in robotics, such as suggesting more optimal task assigning or resource managing plans [39]. Sealing these gaps will entail bridging reinforcement learning, planning algorithms, and multi-agent coordination architectures with XAI in a way that explanations are both operationally effective and human-understandable for robots.

1.1.4. Recommendation Systems for Efficiency Enhancement

1.1.4.1. Overview of Recommendation Systems

Robotics recommendation systems are decision support mechanisms that provide best action prescriptions with the information at hand. Unlike traditional recommendation systems for personalization, in robotics they are also optimized for enhancing workflow performance. For object sorting tasks, it entails finding the optimal sequence of actions to minimize time consumed and maximize throughput. More recent work has married machine learning algorithms with sensor data to create learning and self-adaptive recommendation systems [40].

1.1.4.2. Industrial and Sorting Applications

In the industrial setting, recommendation systems have found application in various tasks to improve productivity. In recycling plants, robots utilize sensor data to choose the best order of sorting, for instance, processing plastics first before metals or glass [41]. Also, in warehouses, robots examine package characteristics such as shape and size and decide on the best handling order to reduce motion complexity and improve throughput [42]. In manufacturing, task assignment becomes optimized by recommending the sequence in which components are combined, optimizing the production process [43]. Such uses demonstrate the potential of recommendation systems to enhance productivity in applications such as robotic object sorting tasks.

1.1.4.3. Real-time Decision Support in Robotics

Real-time decision support in robotics heavily relies on sensor inputs to perceive the environment.

- RGB and Industrial Vision Cameras: These sensors detect visual characteristics such as color and shape, which help in object classification.
- Depth Sensors (e.g., Intel RealSense, LiDAR, Stereo Cameras): These sensors provide 3D data, which helps in detecting object sizes and spatial orientation.
- Spectral/Infrared Sensors: These sort by reflectance properties, useful for distinguishing between metals and plastics.
- Force-Torque or Weight Sensors: These detect material weight, useful in sorting heavy versus light objects.
- Proximity and Ultrasonic Sensors: These detect object presence and relative location, useful for path planning and collision avoidance.

By integrating data from such sensors, robots can calculate object counts per category (material, shape, size), as the basis for recommendations like prioritizing the sorting of plastic balls over others due to their abundance or postponing sorting metal boxes due to their weight and fewer quantities [44]

1.1.4.4. Task Scheduling and Prioritization in Robotics

Robotics task scheduling is strictly an advising task—choosing the best sequence of actions. There are various techniques employed in robotic sorting:

- Heuristics: Low-level regulations like putting the biggest type first or handling fragile items (e.g., glass) first to prevent breakage risk.
- Spatial Reasoning: Having higher priority for closer objects to minimize travel distance.
- Time-based Logic: If there is a moving conveyor belt, having higher priority for products that risk getting pushed out of the workspace.

These scheduling recommendations optimize efficiency and reduce task completion time [45].

1.1.4.5. Rule-based + ML Hybrid Recommendation Approaches

Hybridizing machine learning (ML) with rule-based systems provides a balance approach to recommendation in robotics. Rule-based systems are easy to understand and excel at handling well-known cases. In contrast, adaptive recommendations using ML can learn best strategies from task history. A balance approach leverages the strengths of both: ML handles object detection and feature extraction, while rule-based heuristics provides recommendations as interpretable and explainable to human collaborators [46].

1.1.4.6. Robotic & Automation Recommendation

Recommendation technologies increasingly find application in various robotic and automation use cases:

- Multi-Robot Systems: Recommendations decide which robot handles which set of objects to achieve optimal task allocation and efficiency.
- Sorting Lines: Optimizing through prioritization can reduce bottlenecks by separating similar items, for maximum throughput.
- Material Handling Robots: Sensors combined with rules facilitate efficient sequencing, for instance, removing fragile glass first to avoid accidents.
- Warehouse Robots: Sizing/shaping items in order of priority for stability when stacking to ensure safer and more efficient operations.

These examples establish the context of how recommendation logic can be directly transferred to robotic object sorting tasks [47].

Despite the advancement, there are still literary gaps. Concern for Task Allocation and Route Planning is one. Existing recommender systems for robotics are primarily focused on task allocation and route planning, whereas there is limited concern for real-time efficiency-oriented recommendations for object sorting.

Then insufficient Real-time Implementations. Few implementations of real-time recommendation systems for dynamic robotic tasks have been made, and this has been identified as an area in need of more research. Insufficient Incorporation of Explainability is another major issue. Almost no studies explain why a recommendation is being produced (Explainable AI), which is crucial in human-robot collaboration. This may be addressed in making more efficient and better-reliability robotic systems [48].

1.2. Research Gap

Recent advancements in Explainable Artificial Intelligence (XAI) have helped a lot in providing transparency, interpretability, and trust in AI systems across many domains. Adadi [49] presented a unified XAI framework for healthcare and outlined the importance of interpretable and reliable decision support for clinicians. While this framework highlights the potential of XAI for critical applications, its methodology was initially designed for static datasets and not real-time decision-making, as required in dynamic settings such as human-robot collaboration.

In finance, Wang et al. [50] investigated the accuracy-interpretable trade-off, highlighting how XAI can improve decision-making for financial prediction complex tasks. Their research was capable of successfully illustrating model explanations to end-users but was primarily limited to tabular data, and issues with multimodal data—visual and sensor inputs—were largely left untackled. Rossi and Nguyen [51] also introduced a hybrid that combined model-agnostic and model-specific XAI techniques in time-series forecasting. Although effective in characterizing temporal patterns, the algorithm struggled to scale, particularly with high-dimensional real-world data for large-scale problems, which restricts its application in robotics where rich environments in terms of sensors provide rich data streams.

In addition, Kumar et al. [52] studied XAI for natural language processing to enhance human-AI collaboration by offering interpretable text explanations for model predictions. Although this research demonstrated the value of human-centered explanations, its usage was limited to text data and did not consider multimodal explanations that include visual, audio, or interactive signals—features crucial for building trust in real-world robotic systems.

While these studies collectively advance the theoretical and applied understanding of XAI, they reveal a number of gaps regarding human-robot collaboration. First, current XAI methods are largely domain-specific and have not been tailored for real-time robotic decision-making in which the action must be explained while it is being taken. Second, multimodal explanations that combine visual, auditory, and textual feedback remain underexplored and fail to hinder effective human understanding and trust. Third, existing XAI approaches fail to provide scalability and dynamic flexibility, which are crucial in robotic sorting activities that must operate in uncertain conditions.

Closing these gaps, this work proposes a dynamic XAI robotic object sorting system with interpretable machine learning models and rule-based heuristics, using real-time sensor readings, and interactive multimodal explanations. With the integration of transparency, flexibility, and human-centered explanations, this work aims to enhance trust, cooperation, and overall task performance in human-robot environments, bridging the gap between human intuition and robotic precision.

Table 1.1: Table of identified research Comparison

Features / Gaps	Adadi [1]	Wang et al. [2]	Rossi & Nguyen [3]	Kumar et al. [4]	Proposed Research
Real-time decision support	✕	✕	✕	✕	✓
Human-robot collaboration	✕	✕	✕	✕	✓
Multimodal explanations (visual/audio/text)	✕	✕	✕	✕	✓

Adaptive strategy recommendations	✗	✗	✗	✗	✓
Interactive natural language queries	✗	✗	✗	✗	✓
Rule-based + interpretable ML integration	✓	✓	✓	✗	✓
Scalability to dynamic / large datasets	✗	✗	✗	✗	✓
Domain-specific adaptability	✓	✓	✗	✓	✓

1.3. Research Problem

Reliability and efficiency take precedence in industrial and collaborative robots to achieve optimal completion of tasks, especially object sorting tasks where multiple factors such as object type, weight, and position must be considered simultaneously. While traditional robotic systems can sort based on predetermined rules or machine learning models, the system's decision-making process is generally opaque, hence creating a massive trust deficit between human operators and robots. Wherever robotic behavior appears random or unclear, human partners would hesitate to implement automated processes, reducing overall productivity and possibly introducing flaws in operations.

Later advances in Explainable Artificial Intelligence (XAI) have shown the capacity to bridge this gap in trust by providing interpretable and transparent models for decision-

making. Past studies have explored XAI inclusion in healthcare, finance, time-series forecasting, and natural language processing. These methods tackle increasing interpretability, model reliability, and user comprehension in their respective fields. However, applying these methods to actual real-time robotics operations is not widespread yet. Existing XAI applications tend to target static or offline scenarios and primarily deliver textual forms of explanations, without comprehensively dealing with the dynamic multimodal setting of industrial robotics.

In addition, most robotics decision support and recommendation in robotics today is task allocation, path planning, or efficiency sorting on the basis of sensor readings. While optimizing throughput while constraining bottlenecking, such systems rarely provide interactive, real-time feedback regarding why robots make specific decisions. This transparency constraint prevents human-robot collaboration because operators are unable to anticipate or understand robot behavior and thus cannot intervene or alter strategies when necessary. Secondly, while hybrid rule-based and machine learning solutions have been implemented, these are rarely designed to react to environmental dynamic changes or dynamically update suggestions in real-time, resulting in performance shortfalls in dynamic industrial settings.

The research problem is therefore to build an Explainable AI-powered decision support system for robotic object sorting that can provide real-time, interpretable, multimodal explanations to human collaborators. Such a system would not only have to optimize task execution but also foster greater trust, security, and collaboration by allowing people to understand, query, and even overrule robot decisions when the need arises. Addressing this problem demands the blending of explainable machine learning models and rule-based heuristics, combining real-time sensor streams for adaptive recommendation, and employing a multimodal interface that supports explanations in text, speech, and graphics. The resolution of this issue will fulfill a significant gap in current robotic literature by integrating efficiency, flexibility, and transparency and, therefore, redefining human-robot collaboration in dynamic and industrial environments.

2. OBJECTIVES

2.1. Main Objective

The purpose of this study is to develop an Explainable AI-driven robotic object sorting system that enhances human-robot collaboration by combining transparent decision-making and real-time, adaptive recommendation. The system combines two primary modules: an Explainable AI (XAI) module and a Recommendation System module, both of which interact with human operators for the purposes of enhanced understanding, trust, and operational efficiency. By offering interpretable explanations and actionable recommendations, the system bridges the gap between robot precision and human intuition in dynamic factory environments.

The major objectives of the components are,

1. A **Recommendation Module** trained on image datasets with embedded reasoning (e.g., object count, reachability, or predefined priority).
2. An **Explainable AI Module** that provides transparent justifications for the recommended actions.

By integrating reasoning-aware recommendations with interpretable explanations, the system aims to bridge the gap between robot efficiency and human intuition, fostering trust, collaboration, and productivity in dynamic sorting environments.

2.2. Specific Objectives

Out of the research gaps in Explainable AI (XAI) for robotics and real-time recommendation systems, the specific research goals of this research are:

- **Develop an Image-Based Training Framework**
  - Build a dataset of object sorting scenarios (e.g., 5,000+ images with varying shapes, colors, and counts).
  - Annotate the dataset with both sorting order and reasoning factors (count, distance, reachability).
  - Train a model capable of learning adaptive sorting strategies from these examples.
- **Implement Object Recognition and Counting**
  - Enable the system to detect and classify predefined objects (e.g., three shapes × three colors) within an image.
  - Provide automated identification of object counts and positions to support real-time recommendations.
- **Design a Reasoning-Enhanced Recommendation System**
  - Generate adaptive sorting recommendations (e.g., which object to sort first, second, etc.) based on trained reasoning.
  - Ensure recommendations adjust dynamically to the objects currently present in the workspace.

- **Integrate Explainable AI for Recommendation Justification**
    - Provide human-readable explanations for each recommendation (e.g., “sorted first because it is closest” or “sent to bin X because it is metal”).
    - Support multimodal formats (text, visual cues, or simple voice-based explanations) for better operator understanding.
- **Assess System Performance and Human Trust**
    - Evaluate system performance in terms of recognition accuracy, recommendation efficiency, and explanation clarity.
    - Conduct user studies to measure operator satisfaction, trust, and perceived collaboration quality.
- **(Optional/Extended) Expand Explainability to Additional Modules**
    - If time permits, extend explanations to other components such as texture-based sorting, gaze tracking, or multi-line object detection.
    - Explore collaborative reasoning where human choices influence and adapt the robot’s decision-making.

3. METHODOLOGY

The methodology of the current research is aimed at designing an XAI-driven Recommendation System for robotic object sorting, trained on an image dataset with reasoning-based labels. It is designed to produce adaptive recommendations for the order in which to sort things and to provide transparent explanations to human operators. In terms of methodology, it was approached by structured pipeline: system design, dataset creation, model development, explanation generation, evaluation, and integration with optional modules.

3.1. System Design and Architecture

The proposed system is built around a modular design that brings together two core components: a Recommendation Module and an Explainable AI (XAI) Layer. The Recommendation Module is trained on annotated images that capture both the arrangement of objects and the underlying reasoning behind their sorting order. Using this training, the module generates adaptive recommendations for the sequence in which objects should be sorted. To supplement this, the XAI Layer translates these recommendations into explanations that are easily understood by humans, e.g., indicating that an object is prioritized first because of its closeness or because there are fewer of its kind compared to others.

The system is designed to carry out object recognition and counting across predefined classes.. Based on such recognition, the Recommendation Module provides reasoning-

aware sorting suggestions, while the XAI Layer justifies the decisions using both text-based justifications as well as visual cues.

This modular approach also ensures future flexibility for extension. New modules, for example, can readily be added to facilitate more advanced sorting missions, such as texture-based sorting, gaze tracking for human–robot collaboration, or parallel processing of many object streams. This flexibility ensures that the system not only addresses the short-term objectives but also establishes a solid foundation for greater capabilities in subsequent projects.

3.2. Data Acquisition and Preprocessing

The data set is supplemented with a hardware imaging and robotic task performance system.

Image Dataset

- Image Collection: At least 5,000 images of pre-determined objects (shape × color × various counts and positions).
- Annotation: Objects appearing in each image are tagged along with their numbers, and the reasoning-based ordering sequence (e.g., smaller groups first, nearest first).
- Object Categories: Restricted to a computationally tractable size (e.g., red/green/blue × triangle/circle/square).

Hardware Setup

- RGB Webcam (HD/1080p) – used for capturing dataset images and live test images of the objects.
- Robot Arm (servo-controlled robotic manipulator) – carries out the sorting operations as per recommendations.
- Arduino/Controller Board – interfaces with the robot arm and sensors.
- Proximity/Distance Sensor (optional) – verifies object locations with respect to the robot arm for testing.
- PC/Workstation with GPU – used for training the recommendation model and running inference for live experiments.

Preprocessing transforms the raw data into structured inputs for the recommendation system. Images will first be normalized for standard size and lighting conditions. Object detection and classification will then identify the predefined shapes and colors. Object counts, spatial locations, and relative distances are features that will be extracted. Reasoning-based labels will then be encoded, mapping each training sample to the respective decision rationale. This organized dataset is the foundation for the recommendation system's development and assessment.

3.3. Recommendation System Development

The purpose of the recommendation system is the focus of this work, acquiring adaptive sorting methods directly from the annotated image dataset. During the training, processed visual features of images such as object class, count, location, and relative distance are fed into the model. Each training example is accompanied by a reasoning-based label, explaining both the recommended sorting order and the reason for the specific order. This supervised learning approach enables the system not only to make a good sorting order prediction but to associate each decision with an understandable reason.

At run time, the learned system scans the current scene perceived by the camera and generates an action ordered list that indicates which object should be sorted first, then second, and so forth. The system is designed to dynamically adapt, re-prioritizing based on objects as they appear or shift into new locations. Most importantly, each suggestion is traced back to its rationale—e.g., the system will indicate that an object is sorted first because it's closer to the robot arm or because it's the smallest group encountered. By incorporating reasoning into training and inference, the recommendation system ensures its recommendations are explainable, adaptive, and consistent with human-like decision-making.

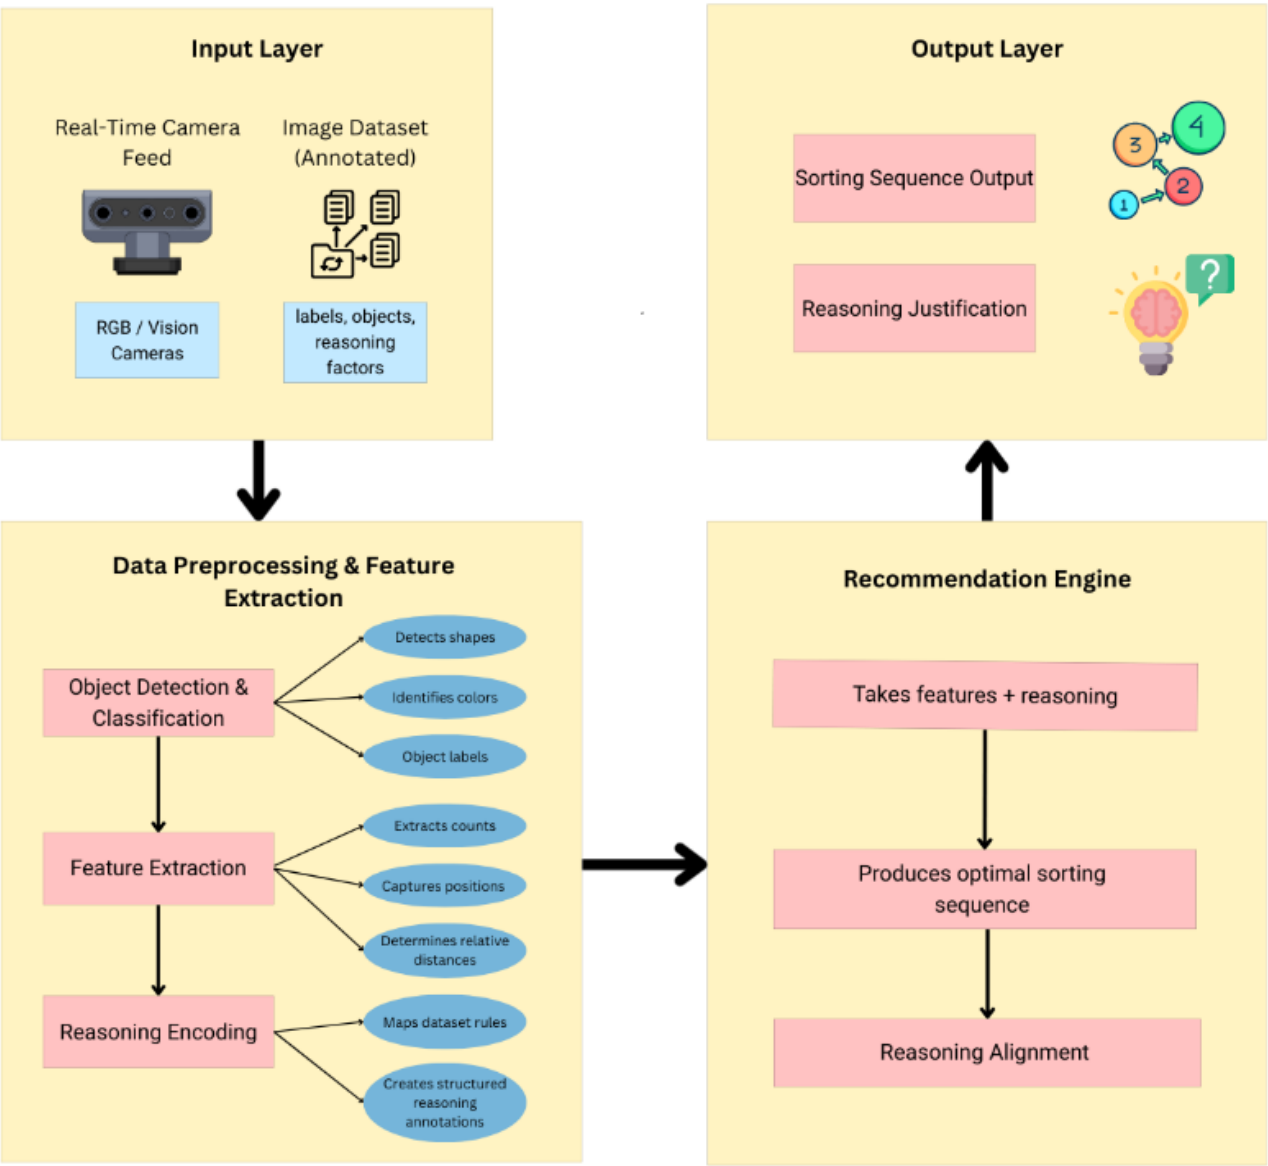

Figure 3.1: Figure of Architecture Diagram of Recommendation System

3.4. Explainable AI (XAI) Layer Development

The Explainable AI (XAI) layer ensures that all the recommendations made by the system are transparent, interpretable, and aligned with human reasoning. The XAI layer bridges the cognitive gap between the autonomous recommendation model and the human operators, fostering trust, collaboration, and accountability in robot-assisted sorting activities.

Explanation Generation

The XAI layer translates raw model outputs into human-understandable explanations. For each recommendation, the system highlights the rationale factors driving the decision, i.e., object quantity, relative distance, or pre-established priority rules. Explanations are communicated in several forms:

- Textual explanations: Concise natural-language justifications (e.g., "The red triangle was selected as it is the closest object within reach").
- Visual overlays: Bounding boxes and highlights on the input image that identify the selected object and emphasize the relevant feature (e.g., distance, color group).
- Reasoning alignment: Explicit mapping between the system's predicted sorting order and the dataset's annotated reasoning labels so that explanations are consistent and traceable.

Multimodal Support

To accommodate different modes of human interaction, the XAI layer supports different explanation channels:

- Text-based explanations are the standard mode, offering simplicity and clarity.

- Visual-based explanations facilitate context-aware comprehension by directly overlaying highlights onto the captured image, allowing operators to immediately grasp why a certain object was chosen.
- Speech-based explanations (optional extension) can be added to provide auditory feedback, increasing accessibility and usability in real-time robot applications.

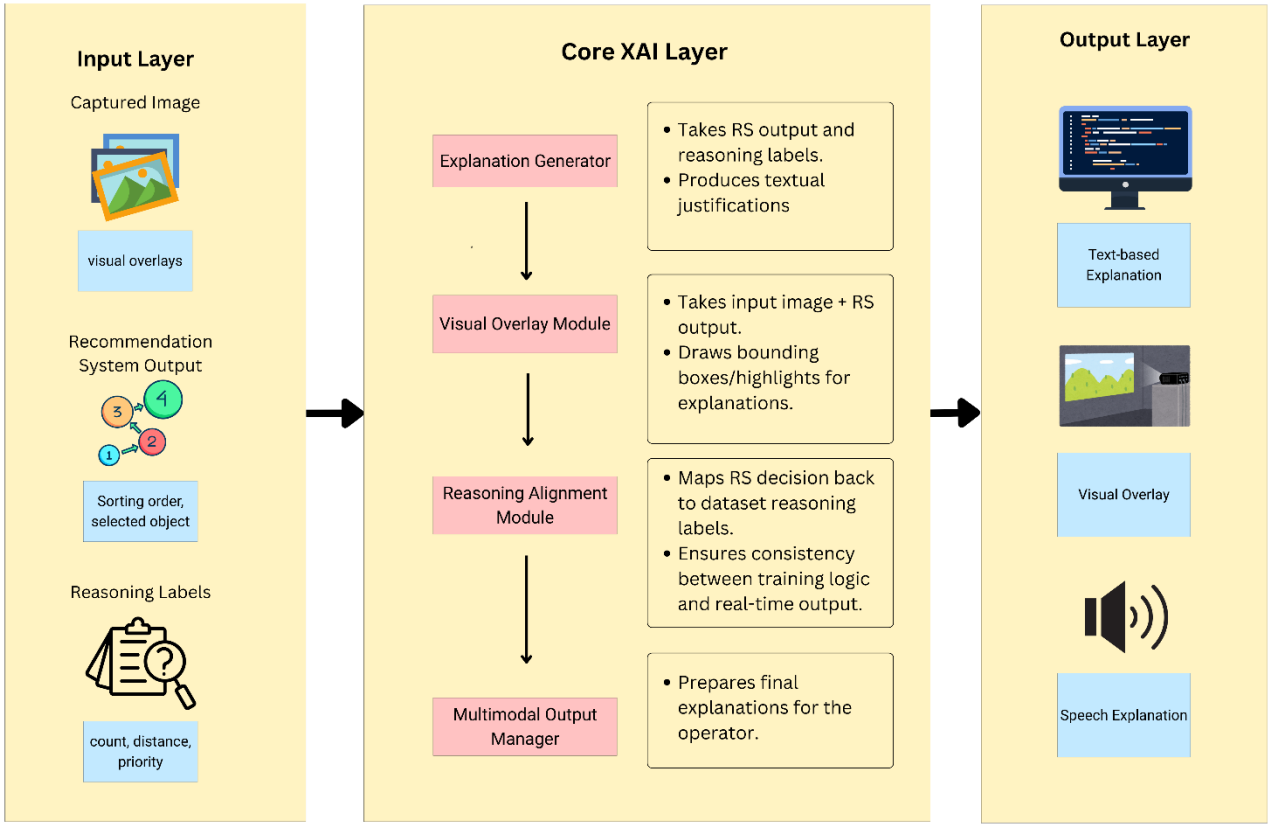

Figure 3.2: Figure of Architecture diagram of XAI Layer

3.5. Evaluation and Testing

The performance of the proposed system will be assessed through a double evaluation framework, where quantitative system-level analysis will be supplemented by qualitative human-centric studies. This approach will guarantee that the system is technically accurate and efficient, as well as usable, interpretable, and trustworthy for human co-workers.

Quantitative Evaluation (System-Level Metrics)

Quantitative evaluation will be employed to emphasize technical accuracy, efficiency, and robustness of the recommendation system and XAI layer:

- Object Recognition Accuracy
  - Quantify object detection and classification accuracy, recall, and F1-score (shapes × colors).
  - Compare system performance against ground-truth set labels.

- Recommendation Correctness
  - Quantify the agreement between system-recommended sorting order and manually annotated ground-truth order.
  - Use rank correlation metrics (e.g., Kendall's Tau, Spearman's Rank Correlation) to approximate sequence similarity.

- Efficiency and Task Performance
    - Quantify task completion times of the proposed system against baseline methods (e.g., random or static sorting).
    - Measure throughput in terms of objects correctly sorted per unit time.

- Scalability and Robustness
    - Stress-test the system with varying numbers of objects and cluttered environments.
    - Test performance under environmental variability such as noise, occlusion, and lighting changes.

Qualitative Evaluation (Human-Centered Metrics)

The qualitative evaluation concerns the interpretability, usability, and trust fostered by the XAI layer:

- Clarity of Explanations
    - Conduct user studies with participants providing ratings on clarity and understandability of explanations via Likert-scale questionnaires.

- Trust in System Decisions
    - Observe the degree to which participants will accept or override recommendations when explanations are provided.
    - Track decision-acceptance rates as an indicator of trust.

- Usability and Cognitive Load
    - Apply standardized measures such as the System Usability Scale (SUS) and NASA-TLX to assess usability and operator workload.

- Comparative Study (Baseline vs. Proposed)
    - Compare the XAI-driven proposed system to a non-explainable baseline.
    - Metrics are task efficiency, sorting accuracy, overrides, and subjective ratings of trust and satisfaction.

Iterative Refinement

The outcome of evaluation will inform iterative system improvement. For instance:

- Unclearly rated explanations will be enhanced by improved natural-language templates or more detailed visual overlays.
- If in situations of crowding efficiency improvements are lost, additional reasoning heuristics can be introduced.

3.6. Integration with Other Modules

Though the Recommendation System and XAI layer are the focus of this research, they function in coordination with:

- Human Behavior Analysis Module: Infers human collaborator actions for coordination optimization.
- NLP Communication Module: Interprets human commands and questions.
- Object Structure Identification Module: Provides knowledge of object features for sorting.

If included, the XAI layer will unify outputs from these modules, but the priority remains on the dataset-driven recommendation + explanation system.

3.7. System Requirements

3.7.1. Functional Requirements

- Detect pre-defined objects from images taken.
- Classify objects by shape and color.
- Extract object count, spatial positions, and relative distances.
- Produce a sorted list of objects for sorting.
- Provide recommendations based on reasoning factors from annotated dataset.
- Update recommendations in real time as the scene evolves.
- Map each recommendation to its reasoning factor.
- Give text explanations of recommendations.
- Give visual overlays highlighting chosen objects and reasoning.
- Optional speech explanations.
- Allow interactive questioning of "Why was this object chosen?" (future extension).
- Send proposed sorting order to robot arm for execution.
- Integrate inputs from other modules (e.g., gaze tracking, texture-based sorting).
- Generate explanations that integrate its reasoning with outputs from external modules.

3.7.2. Non-Functional Requirements

- The system must ensure real-time responsiveness, so explanations are generated within a few seconds of an action.
- The system must maintain high reliability and safety, preventing hazardous or unsafe robot actions.
- The system must provide high interpretability, ensuring explanations are understandable to non-technical users.
- The system must be scalable, supporting additional robots, sensors, or new ML models.
- The system must ensure usability, providing simple and clear interaction methods for operators.
- The system must maintain robustness, continuing to operate even if some sensors or modules fail.
- The system must ensure data privacy and security, protecting sensitive operational and user data.
- The system must be maintainable, allowing easy updates to models, heuristics, and interfaces.

4. DESCRIPTION OF PERSONAL AND FACILITIES

Research and Development Team

The Research and Development Team will create, execute, and evaluate the proposed Explainable AI-based Recommendation System. The team combines expertise from different fields, including,

- Object recognition and sensor integration for accurate perception of size, shape, and weight.
- Human-robot collaboration modules, e.g., NLP for interactive communication.
- Recommendation system creation for real-time object sorting.
- Development of an explainable AI model for explainable robotic decision-making.

Robotics Specialists and Technical Support

A robotics specialist has been identified to assist in designing, integrating, and maintaining the robotic hardware and sensors. Their expertise ensures safe operation, proper placement and deployment of sensors, and smooth integration of the Recommendation System with the XAI modules. Additionally, the specialist provides guidance on technical challenges that may arise during implementation.

Academic Community and Supervisors

The research will also be guided and evaluated by the scientific community, including the supervisor and co-supervisor. Through their intervention, there will be ensured scientific validity, methodological quality, and compliance with research best practices. The research outputs can also provide relevant knowledge to consider for future works on robotics, human-robot interaction, and Explainable AI.

Beneficiaries

Upon successful implementation, the proposed system will have a direct impact on.

- Industrial workers in various regions will experience enhanced efficiency and reliability in object sorting processes, reduced manual labor, and fewer errors.

5. BUDGET AND BUDGET JUSTIFICATION

The proposed budget contains specific allocations which will enable the successful deployment of the multimodal human–robot communication framework. The robotic arm receives the largest funding because it performs sorting operations and proves the system's effectiveness in actual use. The system uses inductive/proximity sensors and ultrasonic sensors and safety sensors to achieve accurate environmental perception and interaction capabilities. The system uses webcams for vision-based object recognition and a dedicated USB microphone to capture high-quality speech for speech recognition operations. The system's ability to adapt to changing conditions depends on supporting devices which include a decibel meter and noise sensor and light sensor. The system operates smoothly because the Arduino board and sensor mounting structures and power supply with cables integrate all components properly. The system includes a miscellaneous supply budget to support assembly work and maintenance activities and unexpected needs which will maintain system robustness and full functionality.

Table 4.1: Table of budget requirement

Tool	Cost (LKR)
Robo Arm	20,000.00
Capacity / Proximity Sensors	6,000.00
Arduino Mega Board	5,000.00
Sensor Mounting Structure	2,500.00
Standard Webcam	3,900.00
USB Webcam (1080p) x 2	11,800.00

UGREEN 9 USB Microphone	7,500.00
Decibel Meter / Light Sensor	4,500.00
Noise Sensor	3,500.00
Power Supply & Cables	9,500.00
Optional Safety Sensors	8,000.00
Ultrasonic Sensor (HC-SR04)	650.00
Breadboard	300.00
Other Supplies	10,000.00
Estimated Total Budget	93,150.00

7. CONCLUSIONS AND RECOMMENDATIONS

This research proposes to construct an Explainable AI-driven robotic object sorting system that integrates adaptive suggestion with interpretable justification to facilitate effective human–robot collaboration efficiency. By constructing a large-scale annotated image database and training a reasoning-aware recommendation model, the system is able to produce context-aware sorting plans that develop adaptively according to real-world situations. The incorporation of an Explainable AI (XAI) layer ensures that each recommendation comes with brief, multimodal explanations, bridging the gap between robotic precision and human instinct.

The methodology will be customized to integrate technical completeness and human-centered evaluation: system-level performance metrics will measure recognition accuracy, sorting efficiency, and robustness, while user studies will assess explanation clarity, trust, and usability. The two-faceted evaluation plan guarantees functional performance and interpretability, bridging the current research gap in explainable robotics.

Last but not least, the system suggested herein does not only aim to improve sorting performance under dynamic conditions but also to build trust and accountability in autonomous decision-making. Scalability is provided by the modular architecture, which can be upgraded in the future to upper-level modules such as gaze tracking, texture-based sorting, or collaborative reasoning. By embedding transparency, adaptability, and explainability, this research takes a step forward in the area of interpretable AI in robotics and paves the way for industrial automation that is safer, more intuitive, and more collaborative.

Recommendations

- Future research needs to explore integrating more sophisticated explainable AI methods, such as counterfactual reasoning, to allow for more insights into the decision-making process.
- The system needs to be implemented in real-world environments with diverse populations to evaluate its robustness, usability, and acceptability.
- Further enhancement to AR interfaces as multimodal explanation generators could further enhance user understanding.
- Collaboration with specialists in fields of application is recommended to refine the layer of rule-based heuristics for specific industrial or societal applications.
- Finally, the system must have ongoing observation and audit channels to encourage fairness, transparency, and ethical compliance as it scales up.
